

Question 1

My CID is 00821349 therefore I have $X = 4$ and $Y = 9$.

$$p = 0.6 + 0.4 \times 4 \times \frac{1}{10} = 0.76$$

$$\gamma = 0.1 + 0.9 \times 9 \times \frac{1}{10} = 0.91$$

Question 2

By initializing the transition probabilities and number of actions as well as the reward for each state, an unbiased policy can be obtained from these initial conditions. The MATLAB code shown in Appendix B firstly defined the state transition probability matrix and reward matrix for this starting climbing MDP. An unbiased policy was then obtained and the value function $V^{\pi^u}(s)$ was also evaluated for each state. The result is shown in Table 1. The values are symmetric with respect to the starting state 4 because for an unbiased policy and only two actions (left and right), the probability of going to either direction are equally likely of 50%.

State	$V^{\pi^u}(s)$
1	0
2	-6.6487
3	-2.9411
4	0
5	2.9411
6	6.6487
7	0

Table 1: Value function for S_1 to S_7

Question 3

3. a

From Question 1 and 2 the probabilities of move or stay and the probability of an unbiased policy to choose move to either direction (left or right) were shown as following:

$$p(\text{stay})=0.24$$

$$p(\text{move})=0.76$$

$$p(\text{Left}_{\pi^u})=0.5$$

$p(\text{Right}_{\pi^u})=0.5$, as there are only two actions (right or left) and the policy is unbiased, the probability of moving in either direction is 50% for each state.

The three state transitions observed from the above MDP are: $\{s4, s5, s6, s7\}$, $\{s4, s5, s6, s7\}$, $\{s4, s3, s4, s5, s6, s7\}$ respectively. To identify the probability of each sequence, following statements were written up:

Trace 1: $s4 \rightarrow s5 \rightarrow s6 \rightarrow s7$

$$p(T1) = 0.5 \times 0.76 \times 0.5 \times 0.76 \times 0.5 \times 0.76 = 0.055$$

Trace 2: $s4 \rightarrow s5 \rightarrow s6 \rightarrow s7$

$$p(T2) = 0.5 \times 0.76 \times 0.5 \times 0.76 \times 0.5 \times 0.76 = 0.055$$

Trace 3: $s4 \rightarrow s3 \rightarrow s4 \rightarrow s5 \rightarrow s6 \rightarrow s7$

$$p(T3) = 0.5 \times 0.76 \times 0.5 \times 0.76 \times 0.5 \times 0.76 \times 0.5 \times 0.76 \times 0.5 \times 0.76 = 0.0079$$

$$\text{Likelihood: } L(\pi_u) = p(T1) \times p(T2) \times p(T3) = 0.055 \times 0.055 \times 0.0079 = 2.39 \times 10^{-9}$$

3. b

The unbiased policy is shown in Table 2 below. State 1 and State 7 are absorbing state which means once access to these two states there is no chance to move out, therefore the policy for them are 0. The rest of states all have unbiased probability of moving to the right or left. To find a policy with higher likelihood than the unbiased policy π^u does for the observed three sequences, only policies of visited states need to be altered. As all three sequences have not reached any state of 1 and 2, these two states can be ignored in this case. Except from State 4, at all the other states took an action of moving to the right. The policy for State 3, 5 and 6 to move to the right can be set to 1 in order to get a maximum likelihood. At State 4, it moved to the right and once to the left.

To calculate the best policy for State 4:

$$\pi(S_3, R) = \pi(S_5, R) = \pi(S_6, R) = 1$$

Assume the policy for State 4 to move to the right $\pi(S_4, R) = k$

$$\begin{aligned} L(\pi_M) &= p(T1) \times p(T2) \times p(T3) \\ &= (kp^3)^2 \times k(1-k) \times p^4 \\ &= k^3(1-k)p^{10} \end{aligned}$$

Write down the first derivative of the likelihood as $\frac{dL}{dk} = 3k^2(1-k) \times -1 \times 0.76^{10}$. Set $\frac{dL}{dk} = 0$ to calculate k when L is maximum.

$$\begin{aligned} 3k^2(1-k) &= 0 \\ k &= \frac{3}{4} \end{aligned}$$

The new π^M which has higher likelihood to observe the three sequences is shown in Table 3.

State	Left	Right
1	0	0
2	0.5	0.5
3	0.5	0.5
4	0.5	0.5
5	0.5	0.5
6	0.5	0.5
7	0	0

The following tables show the policy evaluations of unbiased policy generated by dynamic programming and an example policy generated by Monte-Carlo method respectively. From the value in Table 5 the convergence to the expected value can be observed. There was still small difference but as more returns are observed from the new episodes, the average should converge more closely to the expected value.

Table 5: Policy Evaluation by Monte-Carlo

Question 5

5. a

V^{π^M} obtained from Question 4.b is evaluated from a Monte-Carlo method, which made an assumption on the next state would be visited according to a probability. Inversely, V^{π^u} obtained from Question 2.a with a known probability distribution on all the possible visited states in the next step. Therefore, V^{π^u} can be regarded as an actual observed data whereas V^{π^M} is the estimated data by a probability. To measure how similar these two sets of values are, mean square error (MSE) could be a reasonable parameter used to evaluate. MSE squares the difference on each data point and accumulate them together to give one single number as the measure.

Figure 1(a) provided an example of graphic comparison of how these two sets of values are similar. From this example it can be observed that V^{π^M} does converges to V^{π^u} . The MSE in this example is 0.9507. This relatively high error could be due to the small number of episodes generated in this case. If 10000 traces were generated and were used to calculate V^{π^M} , the error could be reduce to below 0.3. A 10000 episodes example shown in Figure 1(b) looks more converged than 10 episodes.

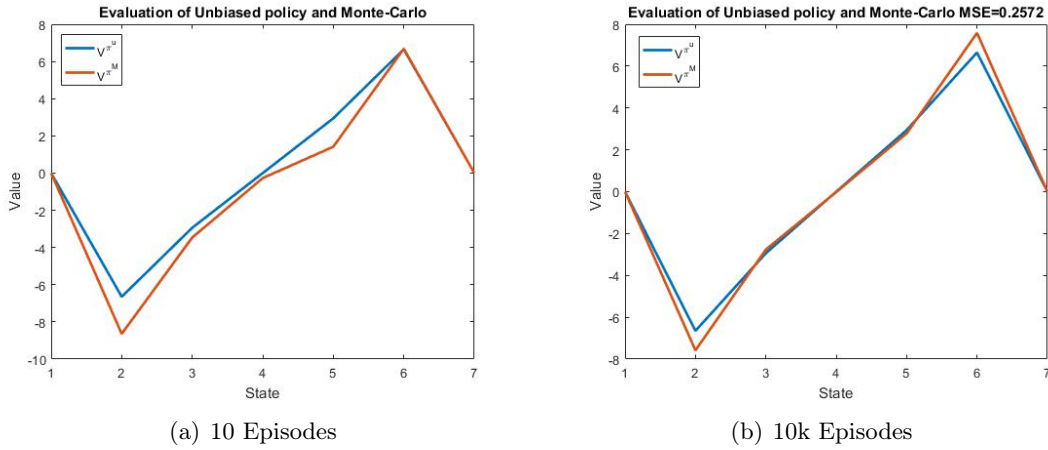

Figure 1: Similarity of V^{π^u} and V^{π^M}

5. b

Randomly selecting actions without reference to an estimated probability distribution could lead to give very poor performance. However if a policy is deterministic, some state-action pairs will only stick with one possibility and some of the others will be never visited which is not ideal in terms of finding greedy policy. Therefore it is necessary to implement an ϵ -greedy policy by setting ϵ as the probability for choosing an action randomly, and $1 - \epsilon$ as the probability for choosing greedy action, to help increase the chance of state-action exploration to get possible maximum Q and thus to carry out an effective policy improvement.

At the beginning of learning, choosing a high ϵ to give high randomness in choosing an action would be potentially beneficial to explore the possible maximum Q which is used to improve the policy. During the learning process, it also helps realise that the current policy is bad. However, if the current policy is already good enough to approach a greedy policy, a high ϵ with too much randomness could lead to a worse performance and therefore take a long time to converge.
